We present a mass map reconstructed from weak gravitational lensing shear measurements over 139 deg² from the Dark Energy Survey science verification data. The mass map probes both luminous and dark matter, thus providing a tool for studying cosmology. We find good agreement between the mass map and the distribution of massive galaxy clusters identified using a red-sequence cluster finder. Potential candidates for superclusters and voids are identified using these maps. We measure the cross-correlation between the mass map and a magnitude-limited foreground galaxy sample and find a detection at the 6.8 σ level with 20 arc min smoothing. These measurements are consistent with simulated galaxy catalogs

based on N -body simulations from a cold dark matter model with a cosmological constant. This suggests low systematics uncertainties in the map. We summarize our key findings in this Letter; the detailed methodology and tests for systematics are presented in a companion paper.

INTRODUCTION

Gravitational lensing refers to the bending of light due to the curvature of space-time induced by massive bodies [1]. This effect allows one to probe the total matter distribution in the Universe, including both luminous and dark matter. Weak lensing is the technique of using the subtle gravitational lensing effect of a large number of galaxies to statistically infer the large-scale matter distribution in the Universe [see [2,3] for detailed reviews]. The measurement is based on small, percent-level “shears”, or distortions of galaxy shapes due to lensing. With several ongoing large optical surveys collecting data [4–7], this technique is one of the most powerful probes for constraining the nature of dark energy [8].

Conventional weak lensing analyses involve calculating the N -point statistics of the shear field. In particular, the *cosmic shear* measurement, which refers to the two-point correlation function of the shear field in configuration space, has been measured in several earlier data sets [9–14]. Shear γ is defined to be a combination of second derivatives of the lensing potential ψ ,

$$\gamma = \gamma_1 + i\gamma_2 = \frac{1}{2}(\psi_{,11} - \psi_{,22}) + i\psi_{,12}, \quad (1)$$

“ $\psi_{,ij} = \partial^2\psi/\partial\theta_i\partial\theta_j$ ” is the second partial derivative with respect to the angular sky coordinates θ_i of ψ (assuming a spatially flat universe in the Newtonian limit of general relativity), which is defined as [15]

$$\psi(\boldsymbol{\theta}, r) = 2 \int_0^r dr' \frac{r-r'}{rr'} \Phi(\boldsymbol{\theta}, r'). \quad (2)$$

In the above equation, r is the comoving distance and Φ is the 3D gravitational potential, whose spatial structure and time evolution contains cosmological information.

Instead of measuring statistics based on shear, here we focus on an alternative approach by converting shear into the projected density field, the convergence κ , also a combination of second derivatives of ψ ,

$$\kappa = \frac{1}{2}\nabla^2\psi = \frac{1}{2}(\psi_{,11} + \psi_{,22}). \quad (3)$$

The convergence directly represents the integrated mass distribution, which can be seen by using the cosmological Poisson equation and the Limber approximation to rewrite Eq. (3) as [2]

$$\kappa(\boldsymbol{\theta}, r) = \frac{3H_0^2\Omega_m}{2} \int_0^r dr' \frac{r'(r-r')}{r} \frac{\delta(\boldsymbol{\theta}, r')}{a(r')}, \quad (4)$$

where H_0 is the Hubble constant today, Ω_m is the total matter density today, a is the cosmological scale factor, and $\delta = (\Delta - \bar{\Delta})/\bar{\Delta}$ is the mass overdensity (Δ and $\bar{\Delta}$ are the 3D density and mean density, respectively). In practice, we integrate over the redshift distribution of source galaxies as shown in Eq. (15) of the accompanying paper [16].

Note that the same weak lensing effect also introduces distortions in the observed cosmic microwave background (CMB) maps. Reconstructing the convergence map from the CMB gives the integrated mass up to the surface of last scattering ($z \sim 1100$). Compared to the weak lensing convergence map constructed from galaxies, the CMB convergence map typically covers a larger area with lower spatial resolution, and the sources of the lensing effect (the CMB photons) come from a single redshift plane [17–19]. In this Letter, we use “weak lensing mass maps” to refer to convergence maps generated from source galaxies.

Weak lensing mass maps supplement measurements based on shear in many ways. Mass maps can be easily cross-correlated with other data since they represent a scalar, the local (projected) mass density, while the shear is a complex variable and is sensitive to the global mass distribution. Cross-correlating with x-ray and Sunyaev-Zel’dovich observations helps us understand the relation of hot gas and dark matter in galaxy clusters. Cross-correlating with the CMB convergence map provides an important cross-check of lensing measurements using different tracers. Other applications of mass maps include peak statistics [20–24], higher-order moments of κ [25], and the identification of superclusters and cosmic voids [26].

The methodology of generating weak lensing mass maps has been demonstrated in earlier work. Massey *et al.* [27] generated a 3D mass map using COSMOS data in a 1.64 deg^2 area. The high-quality shear measurements and redshift information allow for good mass reconstruction on small scales and in the radial direction. Van Waerbeke *et al.* [28], on the other hand, focused on larger-scale information and generated 2D wide-field mass maps from four fields of size $25\text{--}72 \text{ deg}^2$ in the Canada-France-Hawaii Telescope Lensing Survey (CFHTLenS). Our work is similar to Van Waerbeke *et al.* [28], but uses one contiguous region of 139 deg^2 from the Dark Energy Survey [DES, [5,29]] data. This is the first step towards building mass maps from the full DES data set.

The data used in this work are part of the Science Verification (SV) data set from DES, an ongoing ground-based galaxy survey that is scheduled to operate from September 2013 to February 2018. The SV data were collected between November 2012 and February 2013

shortly after the commissioning of the new wide-field mosaic camera, the Dark Energy Camera [DECAM, [30–32]] on the 4 m Blanco telescope at the Cerro Tololo Inter-American Observatory (CTIO) in Chile. This data was used to test survey operations and assess data quality. The images are taken in five optical filter bands (*grizY*) on a total area of $\sim 250 \text{ deg}^2$ and reach close to the expected full depth of DES at $r \sim 23.9$.

The main goal of this work is to reconstruct the weak lensing mass map from shear measurements of the DES SV data in a 139 deg^2 contiguous region overlapping with the South Pole Telescope Survey (the SPT-E field). We present the methodology used for the map construction, followed by cross-correlation results and conclusions. Throughout the Letter, we adopt the following cosmological parameters: $\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$, $\Omega_k = 0.0$, $h = 0.72$. A detailed account of this work can be found in a companion paper in PRD [16].

METHODOLOGY

Data and simulations: Our galaxy samples are based on the DES SV Gold catalog (Rykoff *et al.* [33]) and several extensions to it. The Gold catalog is a product of the DES Data Management [DESDM, [34–37]] pipeline version “SVA1” (Yanny *et al.* [38]), which includes calibrated photometry and astrometry, object morphology, object classification, and masking of the coadd SV images. DESDM utilizes the software packages SCAMP [39], SWARP [40], PSFEX [41], and SExtractor [42] in the pipeline.

Several additional catalogs are used in this work. We use a photometric redshift (photo- z) catalog from the photo- z code Bayesian Photometric Redshifts [BPZ, [43,44]]. We use two shear catalogs from the NGMIX code [45] and the IM3SHAPE code [46]. The two independent shear catalogs allows us to assess the robustness of the measurement. The shear measurement algorithms operate on single-exposure images and measure the galaxy shapes, or “ellipticities”, by jointly fitting the images of the same galaxies obtained in different exposures with one galaxy model and the different point-spread-function (PSF) model in each image. The resulting ellipticity is a noisy estimator for shear [2]. The shear estimates used in this work have been tested rigorously as described in Jarvis *et al.* [47].

We extract from these catalogs background (“source”) and foreground (“lens”) galaxy samples. The objective is to construct the convergence, or mass map, from the background sample and cross-correlate it with the weighted galaxy map built from the foreground sample. Table I lists the final selection criteria for the samples. The foreground sample is magnitude limited at $i = 22$, while the background sample is selected through a series of lensing tests (Jarvis *et al.*, [47]) and is not complete. The incompleteness of the background sample affects only the spatial

TABLE I. Catalogs and selection criteria used to construct the foreground and background sample for this work, and the number of galaxies in each sample after all the cuts are applied. The redshift cut is based on the mean redshift output from the BPZ photo- z code and the magnitude cut is based on the MAG_AUTO parameter in the SExtractor output.

Input catalog	Background (source)		Foreground (lens)
	NGMIX	IM3SHAPE	SVA1 Gold
Photo- z	$0.6 < z < 1.2$		$0.1 < z < 0.5$
Selection	“Conservative additive”		$i < 22$
Number of galaxies	1 111 487	1 013 317	1 106 189
Number density (arc min^{-2})	2.22	2.03	2.21
Mean redshift	0.826	0.825	0.367

distribution of the noise on these maps but does not bias the signal. In the companion paper, we describe in detail the construction of these samples and also discuss a second foreground sample composed of luminous red galaxies. Note that the plots in this Letter rely on the NGMIX shear catalog. However, we analyzed both shear catalogs to assess their statistical consistency. The “conservative additive” selection criteria on the background sample involves a combination of signal-to-noise (S/N) ratio cuts, size cuts, and other quality cuts.

To facilitate our understanding of possible systematics in the procedure of constructing the mass map, we use a set of simulated galaxy catalogs that we match closely to the characteristics of the data (including intrinsic galaxy properties, galaxy number counts, noise, photo- z errors, survey mask). We use the simulated galaxy catalogs developed for the DES collaboration [48]. The catalog is based on three flat Λ CDM (cold dark matter model with a cosmological constant) N -body simulations with different resolutions. Galaxies are populated using the prescriptions derived from a high-resolution simulation using SubHalo abundance matching techniques [48–50]. Photometric properties for each galaxy are then assigned so that the magnitude-color-redshift distribution reproduces that observed in the SDSS DR8 [51] and DEEP2 [52] data. Weak lensing parameters (shear and convergence) are assigned to each galaxy based on the high-resolution ray-tracing algorithm Curved-sky grAvitational Lensing for Cosmological Light conE simulationNS (CALCLENS) [53]. Details of the data and simulation catalogs are presented in the companion paper.

Mass and weighted galaxy maps: Equations (1) and (3) can be Fourier transformed to get a simple relationship between the Fourier transforms of the shear and convergence, denoted $\hat{\gamma}$ and $\hat{\kappa}$ [54]:

$$\hat{\kappa}_\ell = D_\ell^* \hat{\gamma}(\ell), \quad (5)$$

$$D_\ell = \frac{\ell_1^2 - \ell_2^2 + 2i\ell_1\ell_2}{|\ell|^2}, \quad (6)$$

where ℓ_i are the components of the angular wave number. The above equations hold for $\ell > 0$.

In practice, we pixelate the shear measurements into a map of 5×5 arc min² pixels and Fourier transform the map. We then use Eq. (5) to obtain $\hat{\kappa}$ and inverse Fourier transform to yield our final real-space convergence map. In an ideal scenario, this reconstructed convergence map does not contain an imaginary component. However, due to noise, the finite area of the map, and masking, a nonzero imaginary component is recovered. We separate the real and imaginary parts of the measured convergence map into E and B modes, or $\kappa = \kappa_E + i\kappa_B$. The B -mode convergence is a useful diagnostic tool for testing systematics, as it should vanish for real lensing signals on a sufficiently large area. Finally, as the uncertainty in this reconstruction is formally infinite for a discrete set of noisy shear estimates, it is important to apply a filter to remove the high-frequency noise [55]. In this work, we apply a Gaussian filter of different sizes. In the companion paper [16], we use simulations to quantify the degradation in κ_E and the level of κ_B expected from the noise and masking in the data. We find that our results are consistent with that expected from simulations.

One of the main goals of this work is to cross-correlate the mass map with the foreground galaxy distribution. For this purpose, we construct a second mass map assuming that the foreground galaxy sample traces the mass

distribution—we refer to this map as κ_g . It is constructed using Eq. (4) with δ replaced by δ_g , the fractional overdensity of galaxy counts. Under the assumption of linear bias (i.e., galaxy overdensities are linearly proportional to the total mass overdensities, which is expected to be valid on sufficiently large scales), the smoothed κ_g is simply a product of the mass map κ with a constant bias factor. For our foreground galaxy sample, the linear bias is valid above 5–10 arc min scales, which is the focus of our study [56]. In practice, the limited redshift range of our foreground galaxy sample means that we cannot expect a perfect estimate of the mass map even if the bias factor were unity.

RESULTS

Figure 1 shows the resulting weighted galaxy map and the E - and B -mode convergence maps generated from the procedure described above. The maps shown are for a Gaussian smoothing of 20 arc min rms. We expect κ_E to correlate with κ_g , while κ_B should not correlate with either of the other maps.

Correlation with clusters: The κ_E map shown in the middle panel of Fig. 1 is overlaid with galaxy clusters detected in the same data using the algorithm Redmapper [57]. Each cluster is represented by a circle with radius proportional to the optical richness λ , which is related to mass via a roughly linear relation (see Rykoff *et al.* [57] for details of the mass calibration of λ). We select only clusters with $\lambda > 20$, which corresponds to mass $\gtrsim 1.7 \times 10^{14} M_\odot$ ($\lambda = 80$ corresponds to mass $\sim 7.6 \times 10^{14} M_\odot$). Visually,

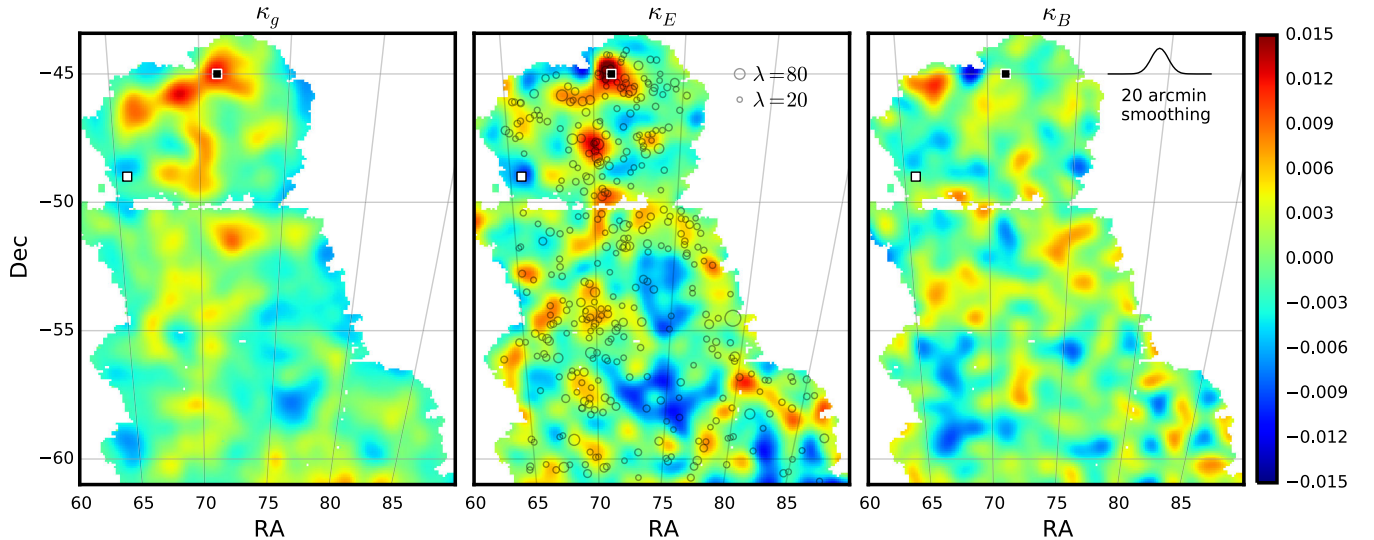

FIG. 1 (color online). The DES SV weighted foreground galaxy maps $\kappa_{g,\text{main}}$ (left), E -mode convergence map κ_E (middle), and B -mode convergence map κ_B (right) are shown in these panels. All maps are generated with 5×5 arc min² pixels and 20 arc min RMS Gaussian smoothing. In the κ_g and κ_E maps, red areas correspond to overdensities and blue areas to underdensities. White regions correspond to the survey mask. The scale of the Gaussian smoothing kernel is indicated by the Gaussian profile on the upper right corner of the right panel. The κ_E map is overlaid by Redmapper galaxy clusters with optical richness $\lambda > 20$. The radius of the circles scale with λ . The black and white squares show the supercluster and supervoid candidate we investigate in Fig. 2.

one can see that the spatial distribution of the clusters traces the mass map very well, with most clusters detected in or around the high κ_E regions.

We analyze the redshift distributions of the clusters in the high and low mass density regions. Two examples are shown in Fig. 2, where we plot (in blue) the lensing efficiency and λ -weighted redshift distribution of the clusters within a 1 deg radius of the identified high and low-mass positions marked in Fig. 1. Compared to the average redshift distribution of clusters (overlaid in grey), we find that the high-mass (low-mass) regions indeed contain many more (fewer) clusters than average. The redshift binning is $\Delta z = 0.03$, corresponding to between $1.5 - 3 \sigma_z$ in this redshift range, where σ_z is the cluster photo- z error uncertainty. The photo- z 's for Redmapper clusters are very well determined [$\sigma_z \approx 0.01(1+z)$], which is important for the identifications of the 3D structures. Using these histograms, we can identify potential candidates for superclusters. For example, the peak at $z \sim 0.14$ in the left panel parked in red indicates that this spatial structure is contained in a redshift range localized to within about 100 Mpc along the line of sight. This line of sight has multiple structures at different redshifts, others have just one or two. The redshift range above $z = 0.6$ (marked with the shaded grey area) overlaps with the background sample; hence, the interpretation of their relation with the mass map is more complicated. The largest mass concentrations are investigated in more detail in the companion paper and in follow-up studies.

Mass-galaxy correlation: Next, we investigate quantitatively the correlation between the foreground galaxies and the mass map by calculating the Pearson correlation coefficient between the two maps over a range of

FIG. 2 (color online). Blue lines show the richness-weighted redshift distribution of Redmapper galaxy clusters along overdense (left) and underdense (right) regions in the convergence map marked by the black and white squares in Fig. 1. The (RA, Dec) positions of the each region is shown in the upper right corner of each panel. The thick grey line shows the average redshift distribution over the full map. Both lines are weighted by the lensing efficiency. The redshift range above $z = 0.6$ (marked with the shaded grey area) overlap with the background sample; hence, the interpretation of the structures there is more complicated.

smoothing scales that span 5 to 40 arc min. That is, we calculate

$$\rho_{\kappa_E \kappa_g} = \frac{\langle \kappa_E \kappa_g \rangle}{\sigma_{\kappa_E} \sigma_{\kappa_g}}, \quad (7)$$

where $\langle \kappa_E \kappa_g \rangle$ is the covariance between κ_E and κ_g , and σ_{κ_E} and σ_{κ_g} are the standard deviations of the two maps. In this calculation, pixels in the masked region are not used. We also remove pixels within 10 arc min of the boundaries to avoid significant artifacts from the smoothing. Similarly, we calculate the Pearson correlation coefficient between κ_B and the other maps to check for any significant systematic effects. The errors on the correlation coefficients are estimated by a jackknife resampling of 10 deg² subregions of the maps (each jackknife subsample is $\sim 93\%$ of the total area).

The results are shown in Fig. 3. We find that the Pearson correlation coefficient between κ_g and the E -mode convergence is 0.39 ± 0.06 at 10 arc min smoothing and 0.52 ± 0.08 at 20 arc min smoothing. This corresponds to a $\sim 6.8\sigma$ significance at these scales. The correlation between the B -mode convergence and the κ_g maps is consistent with zero at all smoothing scales. The correlation between the E - and B -modes convergence is also consistent with zero. The grey shaded regions show the 1σ range of results from the simulated galaxy catalogs modeled to match the main characteristics of the data samples. The black data points

FIG. 3 (color online). The Pearson correlation coefficient between the foreground galaxy and convergence maps is shown as a function of smoothing scale. The solid and open symbols show correlation coefficients from the E and B modes of the convergence, respectively. The grey shaded regions show the 1σ bounds from simulations for the correlation between the E - and B -mode convergence and the foreground galaxies, with the same pixelization and smoothing as the data as well as sources of statistical uncertainty. The green points show the correlation between E and B modes of the convergence map. The various correlation coefficients with the B -mode convergence are consistent with zero. Uncertainties on all measurements are estimated using jackknife resampling.

agree well with the simulations, suggesting there are no significant contributions to our signal from systematic errors.

To further examine the potential contamination by systematics in the maps, we construct maps of 20 quantities associated with the observing conditions (e.g., airmass, extinction, seeing, PSF ellipticity, etc.) and cross-correlate with our κ_E and κ_g maps. We find that none of these quantities contribute significantly to the cross-correlation signal we have measured, with most of them consistent with zero. Details are presented in the companion paper.

SUMMARY

We present in this Letter a weak lensing convergence map generated from shear measurements in the 139 deg² SPT-E field in the Dark Energy Survey science verification data. The mean redshift of the source galaxies is 0.82 and corresponds to a comoving distance of 2.9 Gpc. This map probes the projected total mass (luminous and dark), with matter approximately halfway between us and the source galaxies making the most contribution to the lensing. We study the correlation of the mass map with galaxies and clusters that trace the foreground mass distribution.

The spatial distribution of galaxy clusters identified in the same data using an independent technique is highly correlated with the mass map. The combination of the mass map and the cluster catalog provide a powerful tool for exploring potential superclusters and supervoids in the Universe. Cross-correlating the E mode mass map with a magnitude-limited foreground galaxy sample gives a 6.8σ detection at 20 arc min smoothing, while the cross-correlation between B -mode mass map and the galaxies is consistent with zero on all scales. The cross-correlation between E - and B -mode mass map are also consistent with zero. These results are consistent with simulations of the Λ CDM model in which we have modeled several sources of statistical uncertainties in the lensing and weighted galaxy maps. More detailed analysis, simulation, and systematics tests are described in a companion PRD paper [16].

Topics for follow-up studies include the study of galaxy bias, identification of superclusters and supervoids, higher order moments of the mass map, and cross-correlation with the CMB and other observations. With the full set of data from DES in a few years (~ 35 times the size of the SV data used in this work), we expect the mass maps to be a powerful tool for cosmology.

We are grateful for the extraordinary contributions of our CTIO colleagues and the DECam Construction, Commissioning and Science Verification teams in achieving the excellent instrument and telescope conditions that have made this work possible. The success of this project also relies critically on the expertise and dedication of the DES Data Management group. We thank Jake VanderPlas, Andy Connolly, Phil Marshall, Ludo van Waerbeke, and Rafal Szeplietowski for discussions and collaborative work

on mass mapping methodology. C.C. and A.A. are supported by the Swiss National Science Foundation Grants No. 200021-149442 and No. 200021-143906. D.G. was supported by SFB-Transregio 33 “The Dark Universe” by the Deutsche Forschungsgemeinschaft (DFG) and the DFG cluster of excellence “Origin and Structure of the Universe”. F.S. acknowledges financial support provided by CAPES under Contract No. 3171-13-2. O.L. acknowledges support from a European Research Council Advanced Grant No. FP7/291329. Funding for the DES Projects has been provided by the U.S. Department of Energy, the U.S. National Science Foundation, the Ministry of Science and Education of Spain, the Science and Technology Facilities Council of the United Kingdom, the Higher Education Funding Council for England, the National Center for Supercomputing Applications at the University of Illinois at Urbana-Champaign, the Kavli Institute of Cosmological Physics at the University of Chicago, the Center for Cosmology and Astro-Particle Physics at the Ohio State University, the Mitchell Institute for Fundamental Physics and Astronomy at Texas A&M University, Financiadora de Estudos e Projetos, Fundação Carlos Chagas Filho de Amparo à Pesquisa do Estado do Rio de Janeiro, Conselho Nacional de Desenvolvimento Científico e Tecnológico and the Ministério da Ciência e Tecnologia, the Deutsche Forschungsgemeinschaft, and the Collaborating Institutions in the Dark Energy Survey. The DES data management system is supported by the National Science Foundation under Grant No. AST-1138766. The DES participants from Spanish institutions are partially supported by MINECO under Grants No. AYA2012-39559, No. ESP2013-48274, No. FPA2013-47986, and Centro de Excelencia Severo Ochoa SEV-2012-0234, some of which include ERDF funds from the European Union. The Collaborating Institutions are Argonne National Laboratory, University of California at Santa Cruz, University of Cambridge, Centro de Investigaciones Energeticas, Medioambientales y Tecnologicas-Madrid, University of Chicago, University College London, DES-Brazil Consortium, Eidgenössische Technische Hochschule (ETH) Zürich, Fermi National Accelerator Laboratory, University of Edinburgh, University of Illinois at Urbana-Champaign, Institut de Ciències de l’Espai (IEEC/CSIC), Institut de Física d’Altes Energies, Lawrence Berkeley National Laboratory, Ludwig-Maximilians Universität and the associated Excellence Cluster Universe, University of Michigan, National Optical Astronomy Observatory, University of Nottingham, Ohio State University, University of Pennsylvania, University of Portsmouth, SLAC National Accelerator Laboratory, Stanford University, University of Sussex, and Texas A&M University. This paper has gone through internal review by the DES collaboration.
